117-340-D CABOC-D Protocol

Comprehensive Anti-Black October Cognitive Defense Protocol
Augmenting Cyber-Security

I. The Tsunami Begins Before the Wave

A vulnerability can exist quietly for months. It may be an exposed software dependency, a poisoned document, a deceptive tool description, a compromised memory entry, or an unsafe interaction waiting for an ordinary workflow to activate it. In a conventional system, the damage may remain local. In an agentic enterprise, an authorized actant can carry the disturbance into decisions, memories, tool calls and relationships with other actants. The initial defect becomes only the first link in a longer causal chain.

"The Black October Tsunami" is GUDIYA's name for the feared convergence of accumulated vulnerabilities, accelerated exploitation, interconnected agentic behavior and a growing backlog of downstream consequences. Not every vulnerability is a deliberately planted weapon, and not every failure becomes a cascade. Yet the combination warrants a continuous defensive doctrine spanning the moments before, during and after an incident.

CABOC-D—Comprehensive Anti-Black October Cognitive Defense—treats the entire lifecycle as one operating problem. A scan alone cannot solve it. Neither can a runtime guardrail nor a postmortem report. Prevention, containment and recovery must inform one another.

The Democratization of Exploitation

Nikesh Arora, CEO of Palo Alto Networks, warned that familiar attacks are becoming faster and accessible to more people. His examples include easier attack-path discovery with open-source LLMs, chaining publicly known vulnerabilities, insecure upstream and downstream partners, marketplaces and supply-chain exposure, and AI-assisted coding that inherits insecure patterns. These are his reported observations, not independently verified global attack statistics.

This changes the economics of Black October. If attack discovery, preparation and execution require less time and expertise, a much larger adversarial population may generate more perturbations per unit time. Novel sophistication is not a prerequisite for systemic danger: old vulnerabilities can become more consequential when exploited at industrial scale and machine speed.

Stability Engineering for Autonomous Cognition
GUDIYA GRID

GUDIYA should distinguish the Adversarial Perturbation Arrival Rate (APAR)—attempted destabilizing events per time interval—from verified compromises. APAR, defensive processing capacity, backlog age, attack-path diversity and downstream coupling together determine whether a manageable security queue can become a cascade. Metrics require carefully defined events, deduplication and evidence; a rising count of alerts alone proves little.

The four HCAS constraints compound this threat:

1. machine-speed time compression shortens response windows;
2. hyper-scale numbers increase the reachable actant population;
3. unbounded domains extend exposure across suppliers, tools and organizations; and
4. Nyquist-related observability limits can hide fast changes between measurements.

CABOC-D must be engineered for all four, rather than assuming that faster signature scanning is sufficient.

II. The Minefield Around the Crown Jewels

A Standoff Cognitive Weapon (SCW) is a working GUDIYA threat category: an adversarial mechanism able to influence an intelligent actant without requiring the attacker to interact directly with the protected system at activation time. A hostile instruction embedded in an otherwise legitimate document may remain dormant until an authorized agent reads it. The agent may then execute a tool, rewrite a plan or misinterpret its authority. No conspicuous network attack need occur at that moment.

The cognitive approaches to Crown Jewels include every reachable artifact and interaction pathway that can influence an authorized actant before it acts upon a protected asset. This perimeter may include supplier records, retrieved pages, workflow memory, tool metadata, API responses and intermediate agent decisions. Protecting the asset without inspecting its approaches leaves an important blind spot.

The absence of an active attack is not evidence of the absence of a prepositioned cognitive mine.

III. One Doctrine, Three Temporal Defenses

BEFORE — Cognitive mine-clearing	SCWS, repository of known SCWs, scope mapping, pre-attachment readiness and containment.
DURING — Cascade defense	Runtime observation, GCID-linked tracing, Rendezvous Management, damping and isolation.
AFTER — Consequence recovery	Cognitive DVR reconstruction, behavioral contamination investigation, controlled reauthorization.

The phases overlap. Runtime anomalies suggest new mine signatures. Forensic discoveries improve the repository. Pre-attachment findings tune monitoring rules. Recovery may trigger a fresh attachment sweep. CABOC-D is a learning loop, not a one-time gate.

Continuous Defense Under Accelerated Attack

The BEFORE, DURING and AFTER phases form one closed-loop operating doctrine, not a linear checklist. A newly validated mine found during forensic investigation must update the shared SCW repository; a

runtime anomaly can trigger immediate resweeping; and recovery may require reattachment under revised authority. Attack democratization increases the importance of automated, carefully validated intelligence sharing without allowing untrusted reports to poison the repository.

The operating rule is to allocate expensive inspections by Crown Jewel proximity, consequence, exposure and confidence. Not every alert can receive full forensic treatment at hyper-scale. Risk-adaptive admission, local damping, preauthorized isolation and evidence-preserving triage are needed to prevent the defense system itself from being overwhelmed.

IV. BEFORE: The Pre-Attachment Cognitive Defense Protocol

Before an enterprise, actant, tool or consequential rendezvous receives Grid attachment authority, GUDIYA establishes its identity, requested privileges, relevant Crown Jewels and authorized scanning scope. The Standoff Cognitive Weapon Sweeper (SCWS) then consults the Grid's versioned repository of known cognitive mines. It searches for recognized attack artifacts, suspicious instruction structures, contaminated tool pathways and other validated indicators.

A practical sequence is: declare the attachment scope; map reachable cognitive approaches; retrieve signed and current SCW intelligence; conduct static inspection and isolated behavioral probes; correlate findings with conventional vulnerability assessment; quarantine or restrict suspect pathways; and issue an evidence-based attachment decision. Probes must use synthetic data, least privilege and isolation from live Crown Jewels.

The decision need not be simply yes or no. CABOC-D can authorize full attachment, provisional attachment with restrictions, remediation before attachment, or denial for unacceptable risk. The assessment must report its scope, freshness, repository version, confidence and residual uncertainty. A clean sweep cannot prove the absence of unknown weapons.

V. The GUDIYA Repository of Known Cognitive Mines

The repository converts one enterprise's validated defensive learning into potential protection for other enterprises. A suspected new SCW is submitted with evidence, sanitized to protect enterprise secrets, tested against benign cases, independently reviewed and, if warranted, published as a signed detection package. Its metadata records provenance, confidence, affected surfaces, versions and rollback procedures.

This shared asset can make Grid attachment valuable from the first day: a new member benefits from intelligence accumulated across the federation. Yet the repository itself becomes a Crown Jewel. Poisoned signatures, overbroad rules, compromised updates and leakage of sensitive source material could create systemic harm. Therefore distribution, review and revocation require independent governance and tamper-evident audit.

Before-Phase Assurance Under High Attack Volume

Pre-attachment SCWS must distinguish a known SCW signature from a suspected novel behavior and from a conventional software vulnerability. Its isolated probes should never exercise production privileges or live Crown Jewels. Signed and versioned repository packages need independent validation, rollback and false-positive testing. An enterprise can receive full, provisional, restricted or denied attachment according to residual risk and evidence freshness.

In the Arora scenario, a supplier's vulnerable connector or a marketplace artifact may be an approach path rather than an attack originating inside the enterprise. The sweep must therefore include authorized

upstream and downstream reachability, while preserving vendor privacy and avoiding claims that all third-party surfaces can be scanned.

VI. DURING: Detect the Local Disturbance Before It Amplifies

A mine can evade a sweep, or a dangerous interaction can arise without a mine. CABOC-D therefore continues after attachment. GUDIYA observes authorized task identities, tool invocations, decision transitions, changes in authority, coupling gain, propagation fan-out and departures from stability envelopes. GCID correlates cognitive tasks; GUCL and F-UDL provide proposed cognition and decision records; the Cognitive DVR supports subsequent reconstruction.

The Grid seeks precursors of cascade: unusual synchronization of agents around a false premise, rapidly increasing tool calls, unauthorized expansion of scope, repeated feedback across APIs, incompatible rendezvous states, or a group drifting together while its members remain mutually consistent. A single anomalous event is not proof of attack; detection must be contextual, uncertainty-aware and resistant to false positives.

Rendezvous Management becomes a major control point. When independently operating actants are about to couple, GUDIYA can verify intent, authority and reference compatibility. If risk rises, the Grid may slow execution, narrow privileges, require revalidation or interrupt the rendezvous. The objective is to prevent a local perturbation from gaining the connectivity and feedback needed to become systemic.

VII. The Runtime Escalation Ladder

Normal	Observe and verify within approved envelopes.
Local Damping	Reduce local rate, permissions or coupling intensity.
Counter-Cascade	Interrupt reinforcement and prevent propagation to adjacent actants.
Cognitive Viscosity	Introduce deliberate friction and renewed approvals.
Breakwater Isolation	Separate compromised or unstable domains from the wider Grid.
Cognitive SCRAM	Stop dangerous cognition or action through authorized emergency controls.

These interventions must be proportionate, logged and reversible where feasible. Emergency controls themselves can cause harm if applied indiscriminately. CABOC-D must defend the defenders by protecting the escalation mechanisms from capture, spoofing and unilateral misuse.

During-Phase Time Compression and Cascade Budget

Runtime defense must measure time to harm, not merely average detection latency. If the fastest damaging interaction can propagate in milliseconds, a centralized review that responds in seconds is too slow. Local sidecars and regional stability cells therefore need narrowly scoped, preauthorized throttling, quarantine and breakwater controls, with retrospective audit and limits against accidental denial of service.

At hyper-scale, GUDIYA should monitor coupling density, fan-out, correlated premise adoption, tool-call bursts and cross-domain rendezvous anomalies. Event-triggered telemetry can complement periodic sampling, but Nyquist's classical theorem does not automatically guarantee observability of nonlinear, non-bandlimited cognitive processes. Unknown dynamics and incomplete evidence should cause confidence reduction and proportionate authority restriction.

VIII. AFTER: The Incident Is Not Over When the Defect Is Patched

Suppose a hostile artifact altered an agent's plan. The entry point is repaired, but the agent has already committed to a supplier, updated a shared memory and instructed another actant to act. The original software state may be clean while the enterprise's cognitive state remains contaminated. This is why CABOC-D includes a full consequence-investigation phase.

The Cognitive DVR and task-linked records help investigators reconstruct the timeline: what the actant encountered, what it inferred, which decisions followed, which tools acted, which other actants were affected and which state persisted. Investigators must distinguish observed facts from inferred causality, preserve uncertainty and avoid treating missing logs as proof that no event occurred.

Controlled recovery involves stabilizing the environment, preserving evidence, tracing affected decisions and memories, revoking compromised authority, repairing defects, correcting contaminated state, validating downstream consistency and restoring authority gradually. Some physical actions and external commitments cannot be rolled back; they require compensating measures and accountable human decisions.

After-Phase Behavioral Consequence Assurance

Accelerated exploitation may create many small incidents whose consequences overlap. The forensic problem is therefore not only tracing one intrusion but untangling multiple concurrent decision chains. GCID, GUCL, F-UDL and Cognitive DVR evidence should link artifacts, decisions, tool actions, memory updates, external commitments and subsequent actant behavior, while marking gaps and uncertain causal inferences.

Closing the software vulnerability is not closing the incident. CABOC-D requires explicit disposition of persistent cognitive contamination, downstream transactions, shared-memory pollution and authority changes. Recovery is staged: contain, preserve evidence, repair and reconcile, independently validate, reauthorize, and watch for recurrence. Evidence from this work must feed the SCW repository only after sanitization and validation.

IX. The Three Debts of Black October

Software Repair Debt	Identify, patch and verify the originating technical defects.
Deployment and Assurance Debt	Prove which systems received fixes and controls, and identify what remains exposed.
Behavioral Consequence Investigation Debt	Trace and repair contaminated decisions, memories, workflows and external commitments after the initial defect is removed.

The third debt is the distinctive agentic challenge. A patch closes a vulnerability; it does not automatically retract a decision, erase a contaminated memory or reverse an external commitment. CABOC-D therefore makes consequence recovery an explicit engineering obligation, not an optional forensic afterthought.

X. Attachment Becomes an Active Value Proposition

CABOC-D changes the economics of Grid membership. An enterprise need not wait for a systemic catastrophe to see the benefit. Its first attachment can produce a documented cognitive security posture, actionable mine-clearing findings, a risk-based authorization decision and access to continuously improving collective intelligence. Subsequent actant attachments and high-consequence rendezvous can trigger narrower, risk-adaptive sweeps.

This value remains a hypothesis until measured. The Grid should track verified detection rates, false positives, time to safe attachment, Crown Jewel approach coverage, time to contain, cascade fan-out, forensic completeness and time to verified recovery. Simulated attacks and independent red-team evaluations must test performance against both known and novel hazards.

CABOC-D effectiveness should be evaluated with controlled adversarial experiments varying APAR, attacker population, actant count, coupling topology, external supplier exposure and sampling gaps. Report detection precision and recall, false-positive disruption, time to safe attachment, time to contain, maximum cascade fan-out, decision-lineage completeness and time to verified recovery.

Compare against baseline cybersecurity controls rather than assuming GUDIYA replaces them. Test unknown SCW variants, poisoned intelligence updates, correlated failures, lost Grid connectivity and simultaneous attacks. A successful demonstration would show that CABOC-D reduces harmful propagation and persistent consequences at acceptable operational cost.

XI. Resilience, Privacy and Governance

The sweeper, repository, decision ledger and emergency controls form a new high-value defensive surface. GUDIYA must not make itself the single point of failure. Signed updates, independent validation, compartmentalized scanning, privacy-preserving sharing, fallback modes, distributed trust and auditability are prerequisites. An unavailable sweeper should not automatically force either unrestricted entry or indefinite exclusion; defined restricted modes may be appropriate.

The Grid should share validated patterns rather than indiscriminately copying confidential enterprise documents. Governance must prevent any one participant from flooding the repository with fabricated mines, silently altering detection rules or manipulating the criteria for attachment.

XII. From Conventional Cybersecurity to Continuous Cognitive Defense: The CABOC-D Distinction

1. The Changing Nature of the Defensive Problem

The emergence of Agentic AI does not render conventional cybersecurity obsolete. On the contrary, cybersecurity remains indispensable for protecting software, infrastructure, networks, identities, data, and enterprise assets against unauthorized access, exploitation, manipulation, and disruption.

However, the introduction of autonomous intelligent actants into Hyper-Complex Adaptive Systems (HCAS) creates a new category of defensive challenge. In conventional cybersecurity, the primary analytical objects are typically vulnerabilities, threats, assets, identities, security events, and incidents. Modern cybersecurity already employs continuous monitoring, automated detection and response, threat intelligence, and ongoing vulnerability management.

CABOC-D introduces an additional analytical object: the evolving cognitive consequence of an event as it propagates through interconnected intelligent actants.
An attack may begin with a familiar software vulnerability. But once an autonomous actant encounters the compromised environment, the resulting disturbance may propagate through its reasoning, memory, decisions, tool invocations, authority relationships, and interactions with other actants.
The initiating vulnerability may be patched while the consequences continue evolving.
This distinction is foundational to the Comprehensive Anti-Black October Cognitive Defense Protocol.
The defensive problem does not necessarily end when the initiating security event ends.

2. Comparative Characteristics: Cybersecurity and CABOC-D

Characteristic	Conventional Cybersecurity	GUDIYA CABOC-D
Primary defensive objective	Protect information systems, assets, identities, and operations against cyber threats	Protect autonomous cognition against hostile influences, destabilizing propagation, and persistent cognitive consequences
Primary analytical focus	Threats, vulnerabilities, events, incidents, and affected assets	Actants, cognitive trajectories, interactions, coupling, cascades, and consequences
System perspective	Asset-, network-, identity-, and system-oriented	HCAS-oriented, emphasizing interactions and collective dynamics
Temporal orientation	Continuous prevention, detection, response, and recovery	Continuous BEFORE–DURING–AFTER cognitive defense with feedback across all phases
Before an incident	Vulnerability scanning, hardening, patching, threat hunting, preventive controls	SCWS mine-clearing, cognitive approach assessment, pre-attachment assurance, shared SCW intelligence
During an incident	Detect, investigate, block, isolate, contain, and respond	Detect cognitive deviations, regulate coupling, constrain cascades, invoke Stabilants and escalation controls
After an incident	Forensic investigation, remediation, restoration, and lessons learned	Cognitive DVR reconstruction, behavioral consequence investigation, state reconciliation, controlled reauthorization
Propagation concern	Lateral movement, compromise spread, data exposure, and operational disruption	Propagation through reasoning, memory, legitimate tool use, transient agent teams, and cross-domain rendezvous
Machine-speed response	Automated security detection and response	Pre-authorized local stabilization, damping, coupling restriction, and cognitive breakwater isolation
Observability	Logs, telemetry, security events, endpoint and network behavior	GCID-linked cognitive traces, decision lineage, coupling dynamics, trajectory and stability-envelope observations
Success criteria	Reduced compromise, effective containment, verified remediation and recovery	Reduced cognitive propagation, bounded instability, consequence closure and verified restoration of trustworthy cognition
Defensive learning	Threat intelligence, detection updates, incident lessons and	Validated SCW repository updates, revised rendezvous conditions, stabilization policies and

	improved controls	cognitive recovery knowledge
Relationship to AI autonomy	Protects AI systems and their supporting infrastructure	Additionally governs the dynamic consequences of autonomous interactions
Institutional purpose	Maintain cybersecurity and operational resilience	Extend resilience into continuous cognitive stability and accountable autonomous operations

The comparison is not intended to imply that cybersecurity lacks continuous defense or consequence management. Rather, CABOC-D proposes to make cognitive state evolution, interaction stability, and downstream consequence assurance explicit, first-class defensive responsibilities.

3. From Security Event Closure to Cognitive Consequence Closure

- Consider an enterprise whose procurement agent encounters a compromised supplier document.
- The document contains a hostile instruction designed to influence the agent's subsequent behavior.
- The agent interprets the instruction as legitimate, modifies its purchasing plan, updates shared memory, and initiates transactions through authorized enterprise tools.
- A cybersecurity platform subsequently discovers the malicious document. The artifact is removed, affected credentials are reviewed, and the initiating vulnerability is remediated.
- From the standpoint of the originating security defect, the immediate remediation may be complete.
- But the procurement agent's modified plan may remain active. Its shared memory may continue influencing other agents. External commitments may already have been created.
- The original security event has ended, but its cognitive consequences have not necessarily ended.
- CABOC-D therefore proposes two complementary closure conditions.
    1. Security Incident Closure (SIC) establishes that the originating security incident has been contained and remediated to the applicable assurance standard.
    2. Cognitive Consequence Closure (CCC) establishes that consequential downstream changes in cognitive state, decisions, memories, authority, workflows, and external commitments have been investigated, addressed, and verified to an acceptable assurance level.
- These are proposed GUDIYA classifications rather than existing cybersecurity standards.
- The distinction is particularly important because some consequences cannot simply be rolled back. A financial commitment, physical action, or externally transmitted instruction may require compensating action rather than technical reversal.
- Repairing the vulnerability is not equivalent to repairing the consequences.

4. Why CABOC-D Must Operate as a Continuous Loop

- CABOC-D's BEFORE, DURING, and AFTER phases are not three independent activities executed once in sequence.
- They form a continuous defensive learning and stabilization loop.
- The BEFORE phase employs the Standoff Cognitive Weapon Sweeper (SCWS), using GUDIYA's validated repository of known cognitive mines to examine authorized cognitive approaches to Crown Jewels.
- The DURING phase monitors cognitive interactions and seeks to constrain dangerous propagation through Rendezvous Management, local damping, controlled coupling, breakwater isolation, and the Grid's escalation ladder.

- The AFTER phase reconstructs decision chains using Cognitive DVR and related records, investigates persistent contamination, supports controlled recovery, and identifies previously unknown threat mechanisms.
- The phases continuously reinforce one another.
- A novel attack discovered during forensic reconstruction may become a validated repository entry. A runtime anomaly may trigger a fresh cognitive sweep. Recovery may require renewed Grid attachment assurance. A newly identified coupling failure may change future Rendezvous Management policies.
- This produces a closed-loop cognitive defense system in which prevention, runtime stabilization, and consequence recovery continuously improve one another.

5. The Importance of Machine-Speed Attack Democratization

- The distinction becomes particularly consequential in the emerging environment described by Nikesh Arora, CEO of Palo Alto Networks.
- His observation that familiar attacks are becoming faster and accessible to more people suggests that the threat environment may be changing not only through increasing technical sophistication, but through increasing attack volume and reduced preparation time.
- AI-assisted vulnerability discovery, attack-path identification, and exploitation may increase the rate at which adversarial disturbances enter interconnected systems.
- For GUDIYA, this introduces the proposed Adversarial Perturbation Arrival Rate (APAR).
- When adversarial disturbances arrive faster than defensive systems can assess and contain them, unresolved risks can accumulate. In an HCAS, their effects may also become dynamically coupled.
- Machine-speed time compression, hyper-scale actant populations, unbounded interaction domains, and Nyquist-related observability limitations compound the challenge.
- Consequently, CABOC-D cannot depend exclusively upon human investigation, periodic scanning, or centralized intervention.
- It requires risk-adaptive automated assessment, local stabilization capabilities, continuous evidence collection, and pre-authorized defensive actions within explicitly governed operating envelopes.

6. Cybersecurity Plus GUDIYA GRID

The appropriate architectural relationship is complementary rather than competitive.

- Conventional cybersecurity continues to provide essential capabilities for preventing, detecting, and responding to cyber compromise.
- CABOC-D builds upon those capabilities by introducing cognitive-specific threat assessment, runtime interaction governance, stability enforcement, and consequence-aware recovery.
- A conventional security platform may identify a compromised tool, suspicious credential, or malicious document.
- GUDIYA additionally seeks to determine whether the compromise has altered an actant's cognitive state, whether that alteration is propagating through legitimate interactions, whether the resulting trajectory threatens a stability envelope, and whether the consequences have been adequately resolved.
- The combined defensive proposition is therefore:
    - Cybersecurity protects the digital infrastructure and its operations. CABOC-D extends protection to the evolving behavior and systemic consequences of autonomous cognition.

- This integration must be demonstrated experimentally. CABOC-D remains a proposed architecture, and its incremental effectiveness over established cybersecurity and AI security controls requires independent validation.

7. The Continuous Cognitive Defense Principle

The following principle is proposed for incorporation into the GUDIYA Cognitome:

Continuous Cognitive Consequence Defense Principle

- The protection of Hyper-Complex Adaptive Systems shall not terminate with the detection, containment, or remediation of an initiating security event.
- The GUDIYA Grid shall seek to maintain continuous defensive awareness across the complete lifecycle of cognitive disturbances: identifying latent hazards before activation, constraining dangerous interactions during operation, and investigating and resolving persistent consequences after the originating event.
- Validated knowledge gained during any phase shall inform the others through governed intelligence sharing, updated operating constraints, and controlled recovery procedures.
- The objective is not merely to close security incidents, but to preserve and restore trustworthy autonomous cognition within acceptable systemic stability boundaries.

Closing Perspective

Traditional cybersecurity and CABOC-D address overlapping but distinct aspects of the same emerging challenge.

- Cybersecurity seeks to prevent and manage compromise.
- CABOC-D additionally seeks to ensure that the consequences of compromise—or other destabilizing disturbances—do not evolve into uncontrolled cognitive cascades.
- The distinction is not simply between event-focused and continuous defense. Modern cybersecurity already operates continuously.
- The deeper transition is from managing security events and incidents to continuously managing the cognitive consequences that may outlive them.
- And that leads to the governing proposition:
- An incident may be closed while its consequences remain alive. CABOC-D exists to ensure that the defensive obligation continues until those consequences have been adequately contained, reconciled, and resolved.

XIII. CABOC-D Continuous Defense Principle

Before attachment, seek and contain known or discoverable cognitive mines. During operation, detect and constrain hazardous interactions before local disturbances become cascades. After an incident, reconstruct decision chains, investigate persistent consequences and restore cognition and authority under controlled assurance. Feed verified learning back into the next sweep.

This principle unifies SCWS, Grid Attachment, Zero-Trust Cognition, Rendezvous Management, Cognitive DVR and the stability escalation ladder. It does not claim invulnerability. It creates a disciplined means to reduce exposure, limit amplification and recover from effects that survive the triggering event.

XIV. Open Engineering Work

Before standardization, GUDIYA must specify SCW taxonomies; repository validation and versioning; sweep scope and freshness requirements; task and decision lineage schemas; criteria for runtime escalation; methods for identifying memory contamination; causal inference under incomplete records; recovery assurance thresholds; and governance for federated intelligence sharing. The doctrine is ready to be articulated, while these mechanisms remain subjects for prototyping and validation.

XV. Closing: From Mine-Clearing to Tsunami Prevention

The metaphor begins with a mine waiting for a footstep. But in a hyper-complex adaptive system, the detonation may become a wave: a decision influences a tool, a tool influences another agent, and a mistaken premise becomes a persistent operational reality. CABOC-D places a sweeper before the gate, breakwaters around live cognition and a forensic recovery capability after the wave.

Traditional cybersecurity seeks to find and remove the mine. GUDIYA must also prevent one activated mine from becoming a tsunami across the Cognitive Field—and repair the consequences that remain after the wave.
