117-362-D The Need For Cognitive Coherence

Why Network-Centric Cognition Needs Its Own Quality-of-Service Revolution

Connectivity enables interaction. Coherence establishes trustworthy relationships. Stability governs the behavior that emerges.

16 November 2026

Lesson from History

For several years of my career, I worked for Call Centers at Kaiser Permanente in Southern California.

- These were days of TDM switches from the PSTN cloud using analog Nortel phones (before IP telephony).
- The analog voice call would arrive from Verizon cloud and land in the IVR application, Member would supply his MRN (member record number), some service would be rendered and if the member wanted more service, the call would be routed to the CSR (customer service representative).
- When this analog call would ring on the CSR's desk, the CRM system would wakeup and pop a screen filled with Member's demographic details.
- In order to ensure that the analog audio call and the digital screen pop were synchronized, an important piece of hybrid technology was needed. It was called the CTI server (Computer Telephony Integration). When that malfunctioned, the agent experienced instability.
- Imagine an agent receiving a telephone call while the corresponding customer record fails to appear. The call is real. The computer is running. The member database may be healthy. What failed is the relationship that makes those independent services behave as one interaction. A human can often repair that relationship manually by asking for an identifier and retrieving the record.
- Now replace the human with a network of autonomous actants operating at machine speed, crossing enterprises and controlling consequential transactions. Who repairs the relationship when the channels disagree?

This chapter begins with the reported November 2026 FAA nationwide ground stop, uses firsthand Kaiser Permanente contact-center experience as a concrete historical analogy, and develops a proposed Cognitive Coherence Fabric for GUDIYA. The fabric is not claimed to exist as a validated product. The engineering aim is to determine what must be built, what existing technologies can be reused, and which novel mechanisms would require research.

1. November 2026 — The FAA ground stop and loss of trusted field information

On November 13, 2026, the FAA reportedly imposed a nationwide departure ground stop after serious radar-information and aircraft-communications inconsistencies. In public remarks the following day, Transportation Secretary Sean Duffy described a preliminary telecommunications failure scenario involving legacy copper/TDM-to-fiber/IP modernization and abnormal connection attempts propagating through network equipment. The reported disturbance impaired confidence in the wider air-traffic-management information environment, prompting precautionary admission control while aircraft already airborne continued to be managed.

The exact initiating defect, network sequence, and forensic root cause should be treated as preliminary until an authoritative incident report establishes them. There is no demonstrated evidence that an air traffic controller saw a radar target belonging to the wrong pilot, or that the FAA used CTI servers of the same kind as a contact center. That is a hypothetical synchronization hazard—not an established description of this event. Nor is there evidence that AI caused the ground stop.

The engineering lesson nevertheless stands: a disturbance at a limited technical location can propagate through shared infrastructure and reduce confidence in a national operational field. A field-level authority may then restrict new activity even though many individual components remain functional. This separates local fault, propagation, information-integrity impairment, and protective ground stop into distinct causal stages.

2. The legacy contact center: three synchronized channels

In the contact-center architecture recalled from Kaiser Permanente operations, a member called through the public switched telephone network. A TDM telephony switch and IVR system handled call setup and member interaction. The IVR requested the Member Record Number (MRN). CTI middleware correlated the telephony event, the IVR-provided member context, and the computer application at the agent desktop. When the call was routed to an agent, the corresponding member record appeared automatically: the phone rang and the right screen popped.

These were not three copies of the same event. Voice delivery, IVR dialogue state, and desktop data retrieval were distinct processes, with distinct timing and failure modes. The integration needed a dependable call-to-member-to-agent correlation, event ordering, freshness, and correct routing. A voice call arriving successfully did not prove that the associated screen belonged to the correct member.

Channel	Primary state	Coherence condition
PSTN / TDM voice	Call identity, routing, agent endpoint	The live call reaches the intended agent
IVR interaction	Captured MRN, call context, dialogue progression	The MRN belongs to that interaction and is transferred correctly
Desktop application	Member record and active agent session	The correct MRN record appears for the corresponding call

3. CTI instability and the manual MRN fallback

When CTI servers destabilized, the organization could fall back to voice-only operations. The agent still answered the telephone, asked the caller for the MRN as needed, typed it into the desktop application, and manually retrieved the member record. The essential mission—serving the member—could continue at reduced efficiency. This was a deliberate change of operating mode, not a claim that synchronization was no longer necessary. The human agent became the temporary correlation and reconciliation mechanism.

The fallback had costs: increased handling time, greater cognitive workload, additional opportunities for identification mistakes, and reduced throughput. It also depended on the voice path, desktop application, and member-record service remaining available. A safe fallback requires identity verification and privacy controls; simply typing an MRN does not by itself establish that a caller is authorized to access a record.

4. From TDM/CTI to IP telephony — convergence without magic

The subsequent transition to Cisco IP telephones and Genesys contact-center switching and orchestration illustrates an architectural migration. Voice media, call signaling, IVR applications, routing, and desktop events could increasingly use IP-based infrastructure, even though they remained logically separate services. This simplified some integration boundaries, enabled software-based orchestration, and made unified monitoring and policy more practical. It did not eliminate the need to correlate call identity, IVR state, Chat state, and agent context.

Early VoIP deployments exposed quality-of-service weaknesses. Delay, packet loss, congestion, and variable packet arrival times produced jitter, gaps, or degraded voice quality. QoS classification, prioritization, appropriate queuing, traffic engineering, RTP-aware buffering, monitoring, and capacity planning improved practical operation. A common IP transport did not create perfect timing; it supplied a substrate on which timing and priority could be engineered.

Vendor attribution requires precision. I recall Cisco IP phones and Genesys technology in the contact-center modernization. The FAA's reported telecommunications incident should not be labeled an L3Harris CTI-server failure without documentary evidence. The similarity is in heterogeneous network integration and the consequences of degraded operational coherence, not in a verified common product or failure mechanism.

5. Why the FAA cannot rely on the call-center fallback

A customer-service caller can often wait while a human retrieves a record. An aircraft in flight cannot be safely governed through an improvised manual matching process with unconstrained delay. Air-traffic control already relies on trained controllers, pilots, established procedures, and contingency operations, but time-critical decisions require reliable surveillance, communication, identity, and separation information within the relevant operational deadline. The FAA ground stop is an example of restricting additional demand when that assurance is in doubt.

The correct analogy is not that air-traffic control literally implements a contact-center screen pop. It is that two or more independently functioning information channels can lose sufficient temporal or referential coherence for the combined operation to become unsafe. Unlike the call center, the acceptable time for detection, manual intervention, and recovery can be much shorter and consequence severity much greater.

6. The GUDIYA problem: no universal human synchronizer

Network-Centric Cognition extends this challenge.

- Cognitive Strike Packages contain Quarterback orchestration, functional actants, and independent Cognitive Escort protection.
- Persistent headless services can support many GCIDs.
- Enterprise systems of record accept or reject transactions, and
- physical operators fulfill obligations on their own timescales.

No human can manually correlate every event across millions of actants and machine-speed commitments. The system needs explicit, automated coherence checks at consequential boundaries.

This does not imply that every internal reasoning step must be synchronized or that humans disappear from governance. Humans can define authority, review exceptional commitments, and investigate failures. But they cannot be the default per-event correlation engine for high-volume autonomous execution.

7. Fourteen logical channels the Grid may need to correlate

These channels are logical functions, not necessarily independent networks. Their interfaces and coherence requirements should be defined per mission and risk envelope.

Logical channel	Representative content	Coherence obligation
1. Human UX	Human instructions, approvals, handoffs	Principal, approved proposal, consent freshness
2. Voice/media	Audio and real-time interaction	Participant identity, media timing, session continuity
3. IVR/dialogue	Dialogue state, identifiers, menu selections	Interaction-to-record correlation
4. Cognitive execution	Agent tasks, tool actions, state transitions	Actant-to-GCID lineage, execution outcome
5. Orchestration	Quarterback plans and delegations	Task causal order and completion semantics
6. Identity/authority	Principal, Actant-ID, GCID, leases	Scope, revocation, credential validity

7. Package composition	Spawning, retirement, dormant headless actants	Manifest version and CEA coverage
8. Inter-actant messaging	Rendezvous, messages, acknowledgments	Correlation, duplication, causal order
9. Enterprise transactions	Orders, payments, reservations, SoR state	Authoritative commit vs uncertain acknowledgment
10. Physical resources	Inventory, logistics, sensors, actuators	Capacity and consequence evidence
11. Reference knowledge	External observations and source claims	Provenance, confidence, freshness
12. Protective telemetry	CEA alerts, stability estimates	Timely detection and trustworthy targeting
13. Grid governance	Admission, quarantine, restrictions, release	Authorized policy version and enforcement
14. Evidence/recovery	GUCL, F-UDL, DVR, reconciliation	Durable lineage and obligation closure

8. What synchronization actually means

The word synchronization covers several different requirements.

- Temporal alignment concerns time bounds and skew.
- Identity correlation ensures an event belongs to the correct mission, actant, person, or physical entity.
- Causal ordering ensures an action follows valid authorization and prerequisite events.
- Transactional consistency establishes what an authoritative system of record actually committed.
- Reference integrity asks whether an observation remains sufficiently fresh and trustworthy.
- Protective synchronization asks whether a restriction reaches its enforcement point before a consequential deadline.

A single global clock cannot satisfy these requirements.

- Some require durable event logs and idempotency;
- others require cryptographic authorization, monotonic versioning, causal metadata, local real-time control, or explicit reconciliation.

GUDIYA should use the weakest consistency model that safely satisfies each consequential action, not impose global strong consistency on the entire Cognitive Field.

9. The three-layer AI-Economy as a synchronization challenge

- Layer 1 is the UX Layer with interoperable Agentic UX and e-Commerce UX. A Human Commitment Gate may transfer a prepared proposal to a human for approval.
- Layer 2 contains shared enterprise commerce and authoritative systems of record.
- Layer 3 comprises physical and economic resources with finite capacity and slower fulfillment dynamics.
- Cognitive intent may arrive at machine speed, transaction commitments at a bounded service rate, and physical consequences over minutes, days, or longer.

1. An agent may observe a timeout while an order has already committed.
2. A Quarterback may mark a task incomplete while inventory is allocated.
3. A CEA may detect retries while the Grid's telemetry lags.
4. The system can be connected and each participant can be locally correct, yet the combined operational picture is incoherent.

The remedy is not a faster database alone: it is identity binding, explicit state uncertainty, authoritative reconciliation, bounded retries, and cross-layer obligation lineage.

10. Quality of Service becomes Quality of Cognitive Coherence

Network QoS manages bandwidth, latency, jitter, loss, and prioritization. The proposed Quality of Cognitive Coherence (QoCC) expands the service objective to the trustworthiness of relationships among independently evolving systems. QoCC is not a replacement for network QoS. It is a higher-level contract built on transport, distributed-systems, security, and control mechanisms.

QoCC dimension	Illustrative service objective	Possible measurement
Temporal freshness	Required evidence is no older than policy permits	Maximum observed age / skew
Causal integrity	Prerequisites and delegations precede action	Causal-violation count
Identity binding	Actions map to correct mission and actant	Unattributed or misbound event rate
Authority freshness	Revocations enforced within deadline	Revocation-to-enforcement latency
Transaction certainty	Uncertain commits are reconciled before retry	Unresolved commit duration
Protective response	Restriction reaches action boundary in time	Detection-to-enforcement latency
Resource coherence	Commitments respect supported capacity	Overcommitment and stale-allocation rate
Recovery coherence	Obligations and state reconciled before resume	Time to verified safe resumption

11. Cognitive Coherence Intervals: useful, but not universal simultaneity

A Cognitive Coherence Interval (CCI) is proposed as a bounded window in which the evidence required for a specified consequential action is simultaneously acceptable under its policy: identity valid, authority current, relevant references fresh enough, required transaction state known or safely constrained, and protective enforcement available. The interval is action-relative; it is not a claim that every participant shares the same instantaneous truth.

A practical admission decision might be: PROCEED, REFRESH EVIDENCE, DEFER, RECONCILE, or RESTRICT. The fabric should identify which evidence failed and whether a safe alternative mode exists. It must avoid a false sense of certainty: evidence can be stale, delayed, forged, or unavailable even when a network link is healthy.

12. Nyquist, event velocity, and the coherence deadline

Nyquist sampling theory applies to band-limited continuous signals: sampling frequency must exceed twice the highest represented frequency to avoid idealized aliasing. Cognitive systems, however, contain discrete, bursty, causally related events that are not generally band-limited. Therefore “sample at twice the agent event rate” is not a valid universal rule. Consequential discrete events require durable capture, correlation identifiers, sequence/causal information, and acknowledgments, complemented by sampled telemetry for continuous variables.

The decisive safety quantity is the end-to-end exposure window: observation latency + detection latency + governance decision latency + enforcement latency. At an illustrative action rate λ and exposure interval T, λT

estimates the number of actions potentially attempted before containment; it is not a count of harmful outcomes. Research must determine deadlines and boundedness conditions for each operation class, and must account for queueing, clock uncertainty, burst behavior, and degraded connectivity.

13. A federated Cognitive Coherence Fabric — candidate architecture

The proposed Cognitive Coherence Fabric (CCF) would sit above existing IP transport and beside, not in place of, authoritative enterprise systems. Its local agents, sidecars, gateways, and domain services would bind consequential events to identities and authority, evaluate freshness and causal dependencies, maintain policy-defined coherence windows, and trigger reconciliation or protective restrictions. Sector and national Grids would receive privacy-preserving summaries and propagation signals rather than every raw event.

The fabric should not become a single central CTI server for the nation. Centralized correlation of every cognitive event would create unacceptable scale, latency, privacy, and common-mode failure risks. The architecture must be federated, with local enforcement able to act when the national Grid is unreachable and with independently testable failure domains.

Fabric function	Existing technology candidates	Research gap
Event backbone	Kafka-like logs, event streaming, pub/sub	Cross-domain causal assurance and bounded evidence loss
Identity and delegation	OAuth/OIDC, workload identity, signed claims	Mission-scoped GCID and multi-actant participation
Temporal metadata	PTP/NTP, logical clocks, vector/hybrid clocks	Action-relative confidence under clock uncertainty
Policy enforcement	API gateways, service mesh, policy-as-code	Coherence-aware consequential admission
Transactional reconciliation	Idempotency keys, outbox, sagas	Obligation lineage across autonomous retries
Protective telemetry	Tracing, metrics, event correlation	Propagation-aware multi-mission observability
Priority delivery	QoS/DSCP, queueing, real-time messaging	End-to-end protective deadline assurance
Recovery controls	Checkpoints, state machines, runbooks	Cognitive Airworthiness and safe requalification

14. New technologies that may have to be developed

A. Cognitive Coherence Envelope (CCE)

A compact, signed, audience-scoped event envelope carrying mission correlation, Actant-ID, authority version, causal prerequisites, freshness bounds, transaction/obligation references, and evidence provenance without exposing the root GCID indiscriminately.

B. Coherence-Aware Admission Controller (CAAC)

A local policy engine that evaluates the evidence required for a consequential action and returns proceed, refresh, defer, reconcile, or restrict, with explicit uncertainty and auditability.

C. Coherence Interval Negotiation Protocol (CINP)

A mechanism for parties with different latency and freshness requirements to negotiate action-specific bounds, fail-safe behavior, and evidence expiration, rather than demanding global lockstep.

D. Protective Cognitive QoS (P-CQoS)

An end-to-end priority and deadline framework for CEA alerts, revocation, isolation, and Grid interventions, including independent enforcement paths and overload behavior.

E. Federated Causal and Dependency Graph

A time-versioned graph connecting missions, actants, services, transactions, resources, and protective dependencies while preserving jurisdiction and privacy.

F. Cross-Domain Reconciliation Engine

An automated process for ambiguous acknowledgments, duplicate attempts, delayed physical outcomes, and orphaned obligations, grounded in authoritative local systems.

G. Coherence Degradation State Machine

Standardized states such as coherent, degraded, uncertain, incoherent, reconciling, and requalified, with measurable entry/exit criteria and mission-specific consequences.

H. Cognitive Coherence Test Harness

A fault-injection and simulation environment that deliberately introduces skew, dropped messages, stale authority, common-mode outages, and correlated retries across the three-layer AI-Economy.

15. A practical operating example: autonomous procurement

Imagine a cognitive mission :

- A Quarterback delegates a purchase to an actant.
- The actant submits the order;
- the enterprise system commits it, but the acknowledgment is lost.
- The actant's local state says "unknown," the system of record says "committed," and a physical warehouse reserves inventory.
- A CEA sees a retry request, but its telemetry arrives later than the transaction.
- A naive system retries and may duplicate the obligation.
- A coherence-aware system marks the transaction UNCERTAIN, suspends duplicate commitment, queries the authoritative record, reconciles the F-UDL obligation, and only then authorizes continuation.
- This is the machine-speed analogue of a call arriving before its associated screen can be trusted.

16. Graceful degradation without a human at every boundary

The CTI fallback succeeded because a human could manually perform the missing association. In GUDIYA, fallback must be engineered: switch from autonomous commit to prepare-only mode; retain local execution while restricting external effects; suspend new delegated authority; require a Human Commitment Gate for selected actions; or enter safe-state and reconciliation. Different domains require different fallbacks. A physical control loop cannot depend on a distant cloud Grid for time-critical braking or shutdown.

The critical distinction is mission continuity versus configuration continuity. The GCID and obligations may persist while the package changes execution mode, replaces agents, or suspends consequential authority. A valid fallback must preserve identity, evidence, and recovery accountability.

17. Vendors and disciplines: a possible engineering coalition

Networking and telecommunications organizations such as Cisco, Genesys, and L3Harris represent relevant pools of expertise in IP networks, multi-channel routing, real-time communications, resilience, and mission systems. Distributed-systems specialists contribute event streaming, causal consistency, transaction design,

and reconciliation. Industrial control and safety engineers contribute deterministic local response and failure analysis. Systems dynamics and complex adaptive systems researchers contribute propagation, feedback, and stability modeling.

No named vendor is asserted to be participating in GUDIYA or responsible for the FAA incident. The proposition is that a coherence fabric would likely require an interdisciplinary engineering program rather than a single new LLM orchestration library.

18. Research program — priority topics

ID	Research topic	Initial research question / deliverable
R1	Formal definition of cognitive coherence	Define state, causal, temporal, authority and obligation coherence; prove limits and counterexamples
R2	Coherence contracts and interval semantics	Specify CCI conditions, expiry, uncertainty, and policy-dependent thresholds
R3	QoCC metrics and service classes	Define latency, jitter, freshness, causal error, and protective deadlines by consequence class
R4	Causal event representation	Compare logical clocks, hybrid clocks, signed event envelopes and durable event logs
R5	Federated identity and privacy	Study GCID-derived references, scoped delegation, revocation and cross-domain correlation
R6	Consequential action admission	Evaluate coherence-aware policy gates against ordinary API gateways and transaction controls
R7	Machine-speed observability	Quantify event loss, aliasing, sampling needs, propagation detection and tail latency
R8	Cross-layer velocity decoupling	Model agentic demand, Layer 2 commitments, and Layer 3 fulfillment constraints
R9	Fault propagation and common-mode risk	Identify shared dependencies, amplification loops, cascading failures and partition behavior
R10	Protective traffic priority	Test alert and intervention delivery under congestion and degraded networks
R11	Disconnected cognitive operation	Develop safe lease expiry, local restrictions, resynchronization and recovery
R12	Automated reconciliation	Resolve unknown commit outcomes, duplicates, partial fulfillment and obligation closure
R13	Coherence-aware CEA design	Define independent evidence, local intervention authority and coverage across headless actants
R14	Grid bootstrap and theater readiness	Establish deployment prerequisites, progressive admission and requalification tests
R15	Formal verification and simulation	Use model checking, distributed-systems fault injection, system dynamics and agent-based models
R16	Human fallback boundary	Determine when human approval is effective versus too slow for safe operation
R17	Performance economics	Quantify coherence overhead, throughput, tail latency, compute cost and operational benefit
R18	Governance and standardization	Define interoperability profiles, conformance tests, audit, jurisdiction and independent oversight

19. Experimental roadmap and falsifiable hypotheses

- Phase 1: Recreate the three-channel CTI pattern in a laboratory with a synthetic call, IVR identifier, and screen-pop service. Inject correlation loss, delay, and partial failure. Measure correct association, time to detect mismatch, and fallback cost.
- Phase 2: Replace the human agent with a bounded autonomous actant and explicit reconciliation logic.
- Phase 3: Expand to several Cognitive Strike Packages and a shared transaction system, including persistent headless actants.
- Phase 4: Introduce a federated coherence fabric and Grid admission controls, then compare outcomes against strong conventional baselines.

Test hypotheses should include:

- (H1) coherence-aware admission reduces duplicate or misattributed consequential actions under partial failure;
- (H2) independent protective evidence reduces time to containment of correlated disturbances;
- (H3) local fail-restrictive policies preserve safer operation under Grid disconnection; and
- (H4) the benefits exceed the latency, complexity, and cost introduced by the fabric.

Negative results must be retained, since the goal is engineering assurance rather than confirmation of a predetermined architecture.

20. Research boundaries and possible failure modes of the fabric itself

The fabric can fail through stale correlation maps, incorrect clock assumptions, misconfigured policy, excessive coordination overhead, loss of protective messages, or compromised authority. Strong consistency everywhere could produce unacceptable latency or deadlock; eventual consistency everywhere could allow unsafe commitments. A fabric that claims omniscience would be a dangerous source of false confidence. The research must evaluate false-positive holds, missed incoherence, propagation through the fabric, and its own failure-domain isolation.

PROPOSED GUDIYA DOCTRINE

The Cross-Domain Cognitive Coherence Principle

Consequential cognitive execution shall preserve sufficiently trustworthy relationships among mission identity, participant authority, causal dependencies, authoritative transaction state, and physical obligations. The availability of individual channels shall not be presumed to establish their collective coherence. Where the required evidence cannot be established within the applicable deadline, the system shall defer, restrict, reconcile, or enter a validated degraded operating mode.

The Quality of Cognitive Coherence Principle

Cognitive systems shall classify coherence requirements by consequence, temporal deadline, and acceptable uncertainty. The Cognitive Coherence Fabric shall provide federated, action-relative assurance without requiring universal synchronous execution. Network QoS, event integrity, authority freshness, and protective enforcement shall be engineered as complementary capabilities, not interchangeable guarantees.

The Graceful Cognitive Degradation Principle

When automated cross-domain synchronization becomes unreliable, mission identity and accountability shall be preserved while the execution configuration transitions to an authorized safer mode. Essential operations may continue where their safety can be demonstrated; otherwise new consequential actions shall be held pending reconciliation and requalification. The loss of automation need not become the loss of the mission.

The Defend-the-Coherence-Fabric Principle

Coherence infrastructure shall be treated as critical protective infrastructure, not as an infallible universal coordinator. Its controls shall be auditable, bounded, federated, independently testable, and resilient to loss of central connectivity and common-mode failure. No single coherence service shall be permitted to become an unexamined national point of instability.

Epilogue — From screen pop to national cognitive field

The older call center taught a practical lesson: when the CTI server stopped making the voice call and the member record agree, a human could repair the association and continue the mission. IP telephony then demonstrated that a common digital substrate, combined with deliberate QoS engineering, could make many previously separate channels operate more reliably together. The emerging Cognitive Field inherits the same architectural challenge but removes the assumption that a human can reconcile every event in time.

The next engineering task is therefore not merely to connect more intelligent agents. It is to establish evidence that their independently evolving realities are coherent enough for consequential action—and to prevent incoherence from propagating into instability. Connectivity enables interaction. Coherence establishes trustworthy relationships. Stability governs the resulting field.

Source, attribution, and research status

Firsthand operational example: Recollection of Kaiser Permanente call-center operations involving TDM telephony, IVR capture of MRN, CTI-driven desktop screen pop, manual MRN fallback, and later Cisco IP telephones with Genesys contact-center technology. This account is presented as an attributed practitioner experience, not independently audited corporate infrastructure history. The FAA account reflects preliminary public descriptions of the November 13–14, 2026 disruption and is not a final technical investigation. No claim is made that FAA radar/voice mismatching or L3Harris CTI failure was proven. The proposed CCF, QoCC, CCI, and GUDIYA doctrines are research constructs, not deployed or validated standards.

Layer 3 – Physical & Economic Resources | Aircraft, facilities, fleets, hubs, inventory, people, and delivery execution
KEY PROPOSED INNOVATIONS
Quality of Cognitive Coherence (QoCC)
Measure and assure cross-channel coherence and trust.
Cognitive Coherence Intervals (CCI)
Bounded time windows for consistent state and synchronized decisions.
Coherence-Aware Admission
Admit, sequence, or defer actions to preserve coherence and stability.
Causal Integrity
Maintain a provable, ordered cause–effect relationship across actants.
Protective QoS
Priority, isolation, and rate control for mission-stable cognition.
Automated Reconciliation
Detect mismatches, realign state, and restore a coherent operating picture.
